**USDA Non-Discrimination Statement**

In accordance with Federal civil rights law and U.S. Department of Agriculture (USDA) civil rights regulations and policies, the USDA, its Agencies, offices, and employees, and institutions participating in or administering USDA programs are prohibited from discriminating based on race, color, national origin, religion, sex, gender identity (including gender expression), sexual orientation, disability, age, marital status, family/parental status, income derived from a public assistance program, political beliefs, or reprisal or retaliation for prior civil rights activity, in any program or activity conducted or funded by USDA (not all bases apply to all programs). Remedies and complaint filing deadlines vary by program or incident.

Persons with disabilities who require alternative means of communication for program information (e.g., Braille, large print, audiotape, American Sign Language, etc.) should contact the responsible Agency or USDA's TARGET Center at (202) 720-2600 (voice and TTY) or contact USDA through the Federal Relay Service at (800) 877-8339. Additionally, program information may be made available in languages other than English.

To file a program discrimination complaint, complete the USDA Program Discrimination Complaint Form, AD-3027, found online at [How to File a Program Discrimination Complaint](#) and at any USDA office or write a letter addressed to USDA and provide in the letter all of the information requested in the form. To request a copy of the complaint form, call (866) 632-9992. Submit your completed form or letter to USDA by: (1) mail: U.S. Department of Agriculture, Office of the Assistant Secretary for Civil Rights, 1400 Independence Avenue, SW, Washington, D.C. 20250-9410; (2) fax: (202) 690-7442; or (3) email: program.intake@usda.gov.

USDA is an equal opportunity provider, employer, and lender.

Any changes to the methods from LCMS version 2020.5 outlined below in this document will be reflected in this list

- Computing platforms
  - No changes

- Model calibration data
  - The sample design utilized land cover classes from Helmer et al. (2002) for stratification.
  - Since vegetation cover loss was very common of PRUSVI (largely due to damage from tropical cyclones), no vegetation cover loss stratum was included.
  - Due to a lack of available Landsat imagery over the region prior to 2000, PRUSVI outputs include model calibration data extending from 2000-2020.

- Model predictor data
  - Landsat and Sentinel 2 data are taken from June 1 – May 31 for a given year (e.g. June 1, 2020 – May 31, 2021 for mapping year 2020) (see Table 3).
  - Elevation data used over Puerto Rico are based on the Digital Elevation Models of Puerto Rico (Taylor et al. 2008) and the National Oceanic and Atmospheric Administration Digital Elevation Model over the US Virgin Islands (Love et al. 2014).
  - Landsat/Sentinel 2 Composites were not used directly as predictor variables.
  - CCDC chiSquareProbability parameter was changed from 0.99 to 0.95 and the minObservations was changed from 6 to 4.
  - Interpolated values from both LandTrendr and CCDC were included as predictor variables to allow for more complete maps (These areas can be removed by using the QA band described below).
  - Landsat thermal data were included as predictor variables.

- Modeling (Supervised Classifications)
  - No changes

- LCMS products
  - Ancillary information on the origin of the annual LCMS product output values are now provided as part of a QA bit layer. This layer includes whether an interpolated value was used to produce the LCMS output, the sensor, and the day of year the value came from.
Executive Summary

The Landscape Change Monitoring System (LCMS) is a remote sensing-based system produced by the United States Department of Agriculture, Forest Service (USFS) for mapping and monitoring changes related to vegetation canopy cover, as well as land cover and land use. Data produced by LCMS extend from 1985 to the most recently completed growing year. LCMS is intended to provide a consistent monitoring method for applications including, but not limited to, post-disturbance monitoring, broad-scale vegetation change, land cover and land use conversion trends monitoring, and sensitive habitat monitoring.

This document details the methods employed to create all map products for LCMS version 2020.5. These methods will be revisited annually to ensure they reflect the best available science. Current methods involve utilizing Landsat and Sentinel 2 data in the Landsat-based detection of Trends in Disturbance and Recovery (LandTrendr) and Landsat data in the Continuous Change Detection and Classification (CCDC) temporal segmentation algorithms. Outputs from these algorithms are used as predictor variables in random forest models that are calibrated using training data from TimeSync. The broad categories of LCMS products are vegetation cover change, land cover, and land use.

All LCMS products are freely available for download at the LCMS website. Users can interactively visualize and summarize the data at the LCMS Viewer.

Background

Our landscape is continually changing. Monitoring change in vegetation cover and conversion of land cover and land use is important for making data-driven land management decisions. The USFS has developed the Landscape Change Monitoring System (LCMS) to consistently monitor changes in vegetation cover, land cover, and land use across the United States from 1984 to present.

The LCMS Science Team initially developed all LCMS methods (Cohen et al., 2018; Healey et al., 2018). This team evaluated the best available science about landscape change detection methods and provided guidance for the adapted operational LCMS methods employed by the LCMS Production Team described in this document.

The Science Team and Production Team jointly re-evaluate the methods annually to ensure the mapping process is still based on the best available science. This document describes the methods used to create LCMS version 2020.5 products. The version naming convention is YYYY.v where “YYYY” denotes the most recent year mapped, and the “v” denotes the version of the methods used. We recreate all map products annually from 1985 to the most recent full growing season. Annual production ensures LCMS methods can be updated when appropriate and all maps will be produced in a consistent manner.

LCMS mapping areas include all the United States and its territories. The first operational set of outputs, included in v2020.5, covers the conterminous United States (CONUS) and southeastern Alaska (SEAK). The v2020.6 covers Puerto Rico and the U.S. Virgin Islands. Future mapping efforts will extend to Hawaii. This document outlines methods used over Puerto Rico and the U.S. Virgin Islands.

The core LCMS products are annual vegetation cover change, land cover, and land use raster maps. Vegetation cover change is broken into slow loss, fast loss, and gain. Since PRUSVI exhibited limited slow loss, a slow loss product was not produced. Change products are intended to address needs centered around monitoring variations in vegetation cover or water extent that may or may not result in a transition
of land cover and/or land use. Land cover products can be used to meet more general land cover monitoring needs over time. Land use products can be used to monitor land use conversion patterns.

**Methods**

**Computing platforms**

LCMS utilizes Google Earth Engine (GEE; Gorelick 2017) through an enterprise agreement between the USFS and Google, for all remote sensing raster data acquisition and processing. GEE is a parallel computing environment that provides access to many publicly available earth observation datasets, along with common data processing methods, and computing infrastructure to process these data. While GEE’s data processing methods are quite extensive, currently it cannot meet the breadth of methods available in common scientific computing platforms such as R and the Python package Scikit-Learn (Pedregosa et al., 2011). Due to these limitations, we use Scikit-Learn for sample design, model predictor variable selection, and model validation.

**Model calibration data**

All supervised statistical models need a set of calibration data (dependent variable or training data), and predictor variables (independent variables) to train the model. The model is then applied to the predictor data where there are no calibration data. This section will outline how LCMS calibration data locations are selected and attributed.

**Model calibration data sample design**

The goal of a sample design is to efficiently sample the expected variability of the dependent variable. Since LCMS maps vegetation cover change, land cover, and land use, the sample design needs to account for expected variability in each of these categories across the US.

Pilot projects we completed throughout the United States revealed that many of the classes, such as vegetation cover loss and impervious land cover, are relatively rare across the landscape. The simple random sample we initially used proved insufficient to capture an adequate proportion of these rare classes. To improve our sampling approach, we moved to a stratified random sample design following the guidance from Olofsson et al., (2014). Specifically, “The recommended allocation of sample size to the strata defined by the map classes is to increase the sample size for the rarer classes making the sample size per stratum more equitable than what would result from proportional allocation, but not pushing to the point of equal allocation.”

Based on this guidance, the design first involves stratifying the landscape using land cover data from Helmer et al. (2002). Since vegetation cover loss was very common of PRUSVI (largely due to damage from tropical cyclones), no vegetation cover loss stratum was included. Final strata and their spatial extent are shown in Figure 1 for CONUS.
We chose the strata shown in Table 1 to adequately sample rare classes that are of specific interest to LCMS applications and/or had high model error in LCMS pilot studies. This includes Non-Forested Wetland and Cloud Forest. Areas such as water and barren typically have low model error, and therefore we allocated fewer samples to those classes.

The final sample size was 1,100 across PRUSVI. We started the final sample count with an allocation halfway between equal and proportional. We set a maximum value of 100 for PRUSVI respectively for each stratum. We then proportionally recursively allocated the remainder. Lastly, we set a fixed sample number of 30 for water and barren (because these are “easier”, less variable classes). We allocated the remaining samples across Non-Forested Wetland and Cloud Forest. Table 1 show the final sample counts by strata.
Table 1. – Final sample counts by strata for PRUSVI calibration sample.

**Calibration Data Collection**

We collected model calibration data using the TimeSync attribution tool (Cohen et al., 2010). TimeSync is a web-based application that allows users to look at a time series of Landsat images, along with available high-resolution images in Google Earth Pro and other ancillary data in the Ancillary Data Viewer web application, which is made at the Geospatial Technology and Applications Center (GTAC), to attribute yearly land cover, land use, and change process at each training point location (figure 2). Due to a lack of available Landsat imagery over the region prior to 2000, PRUSVI outputs include model calibration data extending from 2000-2020.
LCMS TimeSync interpretation utilizes the Land Change Monitoring, Assessment, and Projection (LCMAP)/LCMS Joint Response Design. This response design provides a consistent method for attributing a common set of classes for change process, land cover, and land use (see supplementary materials in Pengra et al., 2020). The classes and their definitions are as follows:

- **Change process**
  - FIRE: Land altered by fire, regardless of the cause of the ignition (natural or anthropogenic), severity, or land use.
  - HARVEST: Forest land where trees, shrubs or other vegetation have been severed or removed by anthropogenic means. Examples include clearcutting, salvage logging after fire or insect outbreaks, thinning and other forest management prescriptions (e.g., shelterwood/seedtree harvest).
  - MECHANICAL: Non-forest land where trees, shrubs or other vegetation has been mechanically severed or removed by chaining, scraping, brush sawing, bulldozing, or any other methods of non-forest vegetation removal.
  - STRUCTURAL DECLINE: Land where trees or other woody vegetation is physically altered by unfavorable growing conditions brought on by non-anthropogenic or non-mechanical factors. This type of loss should generally create a trend in the spectral signal(s) (e.g., NDVI decreasing, Wetness decreasing; SWIR increasing; etc.), however the trend can be subtle. Structural decline occurs in woody vegetation environments, most likely from insects, disease, drought, acid rain, etc. Structural decline can include defoliation events that do not result in mortality such as in Gypsy moth and spruce budworm infestations which may recover within one or two years.
  - SPECTRAL DECLINE: A plot where the spectral signal shows a trend in one or more of the spectral bands or indices (e.g., NDVI decreasing, Wetness decreasing; SWIR increasing; etc.). Examples include cases where: a) non-forest/non-woody vegetation
shows a trend suggestive of decline (e.g. NDVI decreasing, Wetness decreasing; SWIR increasing; etc.); or b) woody vegetation shows a decline trend that is not related to the loss of woody vegetation, such as when mature tree canopies close resulting in increased shadowing, when species composition changes from conifer to hardwood, or when a dry period (as opposed to stronger, more acute drought) causes an apparent decline in vigor, but no loss of woody material or leaf area.

- **WIND/ICE**: Land (regardless of use) where vegetation is altered by wind from hurricanes, tornados, storms, and other severe weather events including freezing rain from ice storms.
- **HYDROLOGY**: Land where flooding has significantly altered woody cover or other land cover elements regardless of land use (e.g., new mixtures of gravel and vegetation in and around streambeds after a flood).
- **DEBRIS**: Land (regardless of use) altered by natural material movement associated with landslides, avalanches, volcanos, debris flows, etc.
- **OTHER**: Land (regardless of use) where the spectral trend or other supporting evidence suggests a disturbance or change event has occurred, but the definitive cause cannot be determined, or the type of change fails to meet any of the change process categories defined above.
- **GROWTH/RECOVERY**: Land exhibiting an increase in vegetation cover due to growth and succession over one or more years. Applicable to any areas that may express spectral change associated with vegetation regrowth. In developed areas, growth can result from maturing vegetation and/or newly installed lawns and landscaping. In forests, growth includes vegetation growth from bare ground, as well as the over topping of intermediate and co-dominate trees and/or lower-lying grasses and shrubs. Growth/recovery segments recorded following forest harvest will likely transition through different land cover classes as the forest regenerates. For these changes to be considered growth/recovery, spectral values should closely adhere to an increasing trend line (e.g., a positive slope that would, if extended to ~20 years, be on the order of .10 units of NDVI) that persists for several years.

- **Land cover**
  - **TREES**: Live or standing dead trees.
  - **TALL SHRUBS (SEAK only)**: Shrubs > 1 m in height.
  - **SHRUBS**: Shrubs.
  - **GRASS/FORB/HERBACEOUS**: Perennial grasses, forbs, or other forms of herbaceous vegetation.
  - **BARREN OR IMPERVIOUS**: a) Bare soil exposed by disturbance (e.g., soil uncovered by mechanical clearing or forest harvest), as well as perennially barren areas such as deserts, playas, rock outcroppings (including minerals and other geologic materials exposed by surface mining activities), sand dunes, salt flats, and beaches. Roads made of dirt and gravel are also considered barren; or b) man-made materials that water cannot penetrate, such as paved roads, rooftops, and parking lots.
  - **SNOW/ICE**: Snow and/or ice.
  - **WATER**: Water.

- **Land use**
  1. **AGRICULTURE**: Land used to produce food, fiber and fuels which is in either a vegetated or non-vegetated state. This includes but is not limited to cultivated and uncultivated croplands, hay lands, orchards, vineyards, confined livestock operations, and areas planted for production of
fruits, nuts or berries. Roads used primarily for agricultural use (i.e., not used for public transport from town to town) are considered agriculture land use.

2. DEVELOPED: Land covered by man-made structures (e.g., high density residential, commercial, industrial, mining or transportation), or a mixture of both vegetation (including trees) and structures (e.g., low density residential, lawns, recreational facilities, cemeteries, transportation and utility corridors, etc.), including any land functionally altered by human activity.

3. FOREST: Land that is planted or naturally vegetated and that contains (or is likely to contain) 10% or greater tree cover at some time during a near-term successional sequence. This may include deciduous, evergreen and/or mixed categories of natural forest, forest plantations, and woody wetlands.

4. NON-FOREST WETLAND: Lands adjacent to or within a visible water table (either permanently or seasonally saturated) dominated by shrubs or persistent emergents. These wetlands may be situated shoreward of lakes, river channels, or estuaries; on river floodplains; in isolated catchments; or on slopes. They may also occur as prairie potholes, drainage ditches and stock ponds in agricultural landscapes and may also appear as islands in the middle of lakes or rivers. Other examples also include marshes, bogs, swamps, quagmires, muskegs, sloughs, fens, and bayous.

5. OTHER: Lands which are perennially covered with snow and ice, water, salt flats and other undeclared classes. Glaciers and ice sheets or places where snow and ice obscure any other land cover call are included (assumed is the presence of permanent snow and ice). Water includes rivers, streams, canals, ponds, lakes, reservoirs, bays, or oceans. This assumes permanent water (which can be in some state of flux due to ephemeral changes brought on by climate or anthropogenic).

6. RANGELAND/PASTURE: This class includes any area that is either a) rangeland, where vegetation is a mix of native grasses, shrubs, forbs and grass-like plants largely arising from natural factors and processes such as rainfall, temperature, elevation and fire, although limited management may include prescribed burning as well as grazing by domestic and wild herbivores; or b) pasture, where vegetation may range from mixed, largely natural grasses, forbs and herbs to more managed vegetation dominated by grass species that have been seeded and managed to maintain near monoculture.

Calibration Data Finalization

Since the classes listed above can be too detailed to model with remote sensing data, we bin (cross-walk) them into larger classes appropriate for the LCMS modeling methods. For PRUSVI, change processes are cross-walked into two final classes:

- Fast Loss
  - Fire
  - Harvest
  - Mechanical
  - Wind/ice
  - Hydrology
  - Debris
  - Other

- Gain
  - Growth/recovery

Land cover requires a different cross-walking approach. All TimeSync plots have a primary land cover class that makes up the majority of the plot. Any additional land cover class that comprises 10% or more
of the plot is assigned as a secondary land cover class. Since a plot may have any number of secondary land cover classes, primary/secondary combinations of interest are modeled separately. We include any primary/secondary combination that is common along typical succession, focusing on pairings with a secondary class that is higher along the successional order. The expected land cover successional order is barren to grass/forb/herb, grass/forb/herb to shrub, and shrub to tree. With this in mind, the primary/secondary land cover combinations we model in LCMS are shown in Table 2.

Table 2. – List of primary and secondary land cover classes modeled in LCMS. Successional classes are grouped and highlighted with italic font. The snow/ice and water classes are not modeled with any secondary land cover classes since they are not likely to be part of vegetation succession.

- Other
- Rangeland or pasture

**Model predictor data**

We use spectral information from Landsat and Sentinel-2 imagery and topographic information from the USGS National Elevation Dataset (NED) for modeling. Descriptions of each of these datasets are provided below.

**Remote sensing spectral data**

**Data preparation**

LCMS uses United States Geological Survey (USGS) Collection 1 Tier 1 Landsat 4, 5, 7, and 8 and Sentinel-2a and -2b level 1C top of atmosphere reflectance data. We do not use surface reflectance data because the Sentinel-2 surface reflectance data available within GEE are terrain-corrected. This makes it difficult to utilize in unison with Landsat surface reflectance data that are not terrain-corrected.
For cloud masking Landsat data, we apply the CFmask cloud masking algorithm (Foga et al., 2017), which is an implementation of Fmask 2.0 (Zhu and Woodcock 2012), as well as the cloudScore algorithm (Chastain et al., 2019). For cloud masking Sentinel-2 data, we utilize the s2Cloudless algorithm. We mask cloud shadows in both Landsat and Sentinel-2 using the Temporal Dark Outlier Mask (TDOM) method (Chastain et al., 2019). All remote sensing data preparation procedures can be accessed in the GTAC GEE data processing and visualization library (GTAC GEE Visualization Python Modules on PyPI, GTAC GEE Visualization Python Modules on GitHub).

Annual compositing
LCMS utilizes cloud/cloud shadow masked data as well as annual composites of these data to meet the needs of the temporal segmentation methods. Annual composite values are the geometric medoid of all values not masked as cloud or cloud shadow from a specified date range for each year. Due to persistent cloudiness in parts of Puerto Rico, such as El Yunque National Park, Landsat and Sentinel 2 data were collected from June 1 – May 31 for a given year (e.g., June 1, 2020 – May 31, 2021 for mapping year 2020) (table 3).

Table 3. – Dates used for annual compositing of Landsat and Sentinel-2 data.

</tbody>
</table>

The geometric medoid is the value that minimizes the sum of the square difference between the median value of each band’s values. This ensures that the center-most value in a multi-dimensional feature space is chosen. The value from all bands is from the same observation date. The bands that we include in the feature space are green, red, near infrared (NIR), first shortwave infrared (SWIR1), and second shortwave infrared (SWIR2). We omit blue because it is more prone to atmospheric scattering and can inappropriately influence the medoid algorithm. Any pixel that does not have a cloud or cloud shadow free value for a given year is left as null and excluded from any map for that year. The 2020 composite images for PRUSVI are shown in figure 3 as an example.
Figure 3. – Example of the 2020 composites used in the Land Change Monitoring System (LCMS). The red, green, and blue channels used in these composites are the second shortwave infrared (SWIR2), near infrared (NIR), and red bands, respectively. The top image shows both Puerto Rico (PR) and the U.S. Virgin Islands (USVI). The bottom image shows a zoomed in view over southern Puerto Rico.

**Temporal segmentation**

The goal of temporal segmentation is to identify periods of time that likely have similar land cover and/or change processes. Since different segmentation methods have advantages and disadvantages, LCMS utilizes the ensemble approach outlined in Cohen et al., (2018) and Healey et al., (2018). Currently, the operational version of LCMS utilizes LandTrendr (Kennedy et al., 2010; Kennedy et al., 2018) and CCDC (Zhu and Woodcock 2014) to segment the prepared time series. LandTrendr requires a maximum of one observation per year (i.e., an annual composite, made from Landsat and Sentinel-2 data), while CCDC utilizes every available cloud and cloud shadow-free observation from the Landsat time series only.

**LandTrendr Methods**

LandTrendr iteratively breaks the time series of annual composites and returns a set of segments. Each segment has a start and end year and a start and end fitted value at the start and end vertices respectively (figure 4).
From this information, we assign each band/index for each year the following values:

- Fitted value
- Difference of that year’s fitted value from the fitted value of the start vertex
- Difference from the start to end fitted value of the segment that year falls in
- The duration of the segment that year falls in
- The slope of the segment that year falls in

LCMS uses the GEE version of LandTrendr outlined in Kennedy et al., (2018). The parameters that are used are the same as those in Kennedy et al., (2018) (table 4).

Further documentation of the LandTrendr method used can be found in the GEE reference documentation.

**CCDC Methods**

CCDC segments the time series by identifying outliers from a harmonic regression model. The idea is that different land cover and/or land use types have distinct seasonality signatures. A departure from the seasonality signature indicates a change (figure 5).
Figure 5. – An example of how Continuous Change Detection and Classification (CCDC) segments a time series of data. The clear observations for band 5 (first shortwave infrared band for Land Change Monitoring System [LCMS]) are shown as dots, while the modeled value is shown as a blue line. Notice the dots depart from the typical values around 2008. CCDC then starts a new model following this departure when a new consistent seasonal pattern is re-established. (Source: Zhu and Woodcock 2014 figure 21)

Input data include all Landsat cloud and cloud shadow-free values. LCMS uses all cosine and sine coefficients from the first three harmonics \(2\pi, 4\pi, \text{ and } 6\pi\); see Zhu and Woodcock 2014) from the CCDC outputs. We do not use the slope and intercept generated by CCDC. Instead, we use the predicted value based on the harmonic model on September 1 in place of the intercept (Figure 6), and the difference between that year and the previous year’s fitted values as the slope. This allows CCDC to work properly within the LCMS annual ensemble framework.

The GEE version of CCDC is used for LCMS. The parameters used are shown in table 5.

Table 5. – Continuous Change Detection and Classification (CCDC) parameters used.

Further documentation of the CCDC methods used can be found in the GEE reference documentation.
Summary
Visualizing how the medoid composites and fitted LandTrendr and CCDC values relate can be quite difficult. Figure 6 attempts to illustrate how these values relate for two example pixels. The pixel depicted in the left column shows a fire event, while the right column shows insect-related tree mortality.

The first row shows the time series of the medoid composite values. Notice how each band relates to the other during the change events. The middle row shows the normalized burn ratio (NBR) (a vegetation index related to moisture levels) fitted CCDC output, along with the annualized CCDC value from September 1 for each year. Notice how CCDC finds a break for the fire example but shows a single long-term declining trend of NBR for the insect-related mortality. The bottom row shows the annual values of NBR from the medoid composites, LandTrendr, and CCDC. This illustrates how all three directly relate to each other. Each is different, but not necessarily right or wrong. Both LandTrendr and CCDC reduce inter-annual noise but identify breaks at different points in time. These are all used in the random forest model outlined below to produce final LCMS products.

Figure 6. – An example of predicted values from a pixel. The left column depicts a pixel with a fire event, while the right column depicts a pixel with insect-related tree mortality. The top row shows the raw spectral bands from the annual medoid composites. The second row shows the Continuous Change Detection and Classification (CCDC) output for the normalized burn ratio (NBR) vegetation index, as well as the annualized values used in the Land Change Monitoring System (LCMS). The bottom row shows the raw NBR, LandTrendr-fitted NBR, and CCDC-fitted NBR values on a single graph. This illustrates how these data complement each other as well as how they differ.

Terrain data
LCMS also uses terrain metrics to provide elevation, slope, aspect, and slope-position information to the model. The specific variables used are:
• Elevation
• Sine (Aspect)
• Cosine (Aspect)
• Slope
• Slope-position (circular kernel with 11 pixel window, 21 pixel window, and 41 pixel window) (Weiss 2001)

The Digital Elevation Models of Puerto Rico (Taylor et al. 2008) was used for Puerto Rico, and for USVI the National Oceanic and Atmospheric Administration Digital Elevation Model was used for USVI (Love et al. 2014). All resampling was performed using cubic convolution.

**Summary**
For PRUSVI, Landsat/Sentinel 2 Composites were not used directly as predictor variables. All other LandTrendr, CCDC and Terrain variables covered in this section are utilized in the methods outlined below. Table 6 shows a full list of all predictor variables considered for modeling (raw composites values not used). Not included in this list is Landsat thermal data that is used as a predictor variable in 2021.7 modeling.

**Table 6. – List of Land Change Monitoring System (LCMS) model predictor variables. Annual values are different for each year of the analysis period, while the single value terrain variables remain constant. Raw composites values were not used.**

**Modeling (Supervised Classifications)**
All supervised classifications for LCMS utilize the random forest modeling method (Breiman 2001). Random forest randomly selects a subset of the predictor variables and training sites in many different classification and regression trees. Each of the many trees predicts a class, which are then aggregated and used to determine the final modeled class.

LCMS utilizes the GEE instance of random forests called “smileRandomForest” for all raster-based classification. Local processing utilized for variable selection and map validation uses the sklearn.ensemble.RandomForestClassifier method.
LCMS uses a separate random forest model for each of the following products:

- **Change**
  - Slow Loss
  - Fast Loss
  - Gain
  - Land cover
    - Trees
    - Tall Shrubs & Trees Mix (SEAK only)
    - Shrubs & Trees Mix
    - Grass/Forb/Herb & Trees Mix
  - Barren & Trees Mix
  - Tall Shrubs (SEAK only)
  - Shrubs
  - Grass/Forb/ & Shrubs Mix
  - Barren & Shrubs Mix
  - Grass/Forb/Herb
    - Barren & Grass/Forb/Herb Mix
    - Barren or impervious
    - Snow or ice
    - Water

- **Land use**
  - Agriculture
  - Developed
  - Forest
  - Non-forest wetland
  - Other
  - Rangeland or pasture

Each of these products has an annual model output that is the proportion of trees within the random forest model that chose that class. For example, if the fast loss random forest model had a total of 100 classification trees in it, and 45 of those trees chose “fast loss” and 65 chose “not fast loss” in 2005, that pixel would have a value of 0.45 in 2005. This model confidence, which can also be thought of as a probability, can have values between 0 and 1 and is available for each model for each year from 1985 to the most recent complete growing season. Figure 7 illustrates this concept in more detail.

**Predictor variable selection**

To reduce predictor variable co-variation and inclusion of variables that do not improve the model, we filter predictor variables in a two-step process. The first step involves filtering out any predictor pairs that have an r-squared greater than 0.95 (pandas.DataFrame.corr). The variable with the lowest mean r-squared across all pairs is retained. The next step is a recursive feature elimination using a 5-fold grouped cross validation (sklearn.feature_selection.RFECV). We retain the variable combination with the highest accuracy for land use and land cover or highest ROC_AUC (Area Under the Receiver Operating Characteristic Curve) score for change. Interpolated values from both LandTrendr and CCDC were included as predictor variables to allow for more complete maps (These areas can be removed by using the QA band described below).
Model validation
We determine an optimum model confidence threshold by assessing the precision and recall at every possible threshold (from 0-100) and selecting the threshold that maximizes both precision and recall. We then use this threshold in a stratified 5-fold cross validation following Stehman (2014) for each change, land cover, and land use model. We use the stratified random sample of 30 m by 30 m plot locations as the sample, and group training points by plot ID so that all training points from the same plot (but that occurred in different years) are always included in the same fold.

Final output creation
As explained in the previous sections, each class within the change, land cover, and land use products has a model confidence score, which represents the proportion of trees within the random forest model that classified a given pixel as that class for that model. Some examples of model confidence time series from individual pixels are shown in figure 7. For each year, the line with the highest confidence is the class that is chosen for the given LCMS product (change, land cover, and land use). For change classes, the line with the highest confidence must also have a value above that model’s threshold. This is done because the “Stable” class is not modeled explicitly.

In figure 7, the pixel time series shown in the left column has been affected by a fire, while the pixel shown in the right column depicts long-term tree mortality from insects. The first, second, and third rows show the change, land cover, and land use time series, respectively.

Beginning with the fire example, the change time series (first row, left column) shows that the fast loss model confidence peaks in the year of the fire (2012), to a value that exceeds the fast loss threshold of 0.29. In the years following the fire (2013-2020), the gain model confidence rises to levels above the gain threshold of 0.29, as one might expect with growth and recovery following a fire. Complementing the change time series, the land cover time series (second row, left column) shows that the tree class had a very high model confidence for each year until the fire in 2012. Following the fire, the tree model confidence goes down, but it remains the most confident class. This often occurs when the trees are damaged or not all burned, but the understory burns. In the following years, we see the probability of grass/forb/herb & trees mix increase, most likely indicating that there are live trees in this pixel with grasses becoming more and more prevalent. Since a fire generally does not indicate a land use transition, the land use forest model’s confidence dips (third row, left column), but remains the highest.

The time series of long-term tree mortality caused by beetles (right column), is quite different. In this case, the slow loss model confidence is elevated for about two decades (first row, right column). While the gain model confidence is elevated slightly during the second decade of this trend, the slow loss model remains the highest. Although there was indeed slow loss at this pixel, there was no transition of land cover or land use classes (second and third rows, right column). It is important to note that many instances of loss and gain do not result in a change of land cover or land use.
Figure 7. – Time series of Land Change Monitoring System raw modeled probabilities for each year for a fire (left column) and tree mortality due to beetles (right column). The first, second, and third rows of this figure show the change, land cover, and land use time series, respectively. The map product assumes the class with the highest confidence for each year. Notice that it is possible to have a change event without a change in land cover or land use.

**LCMS products**

We package the final LCMS deliverables in two ways: annual and summarized layers. For each product (change, land cover, and land use) we assemble annual maps, as discussed above. We only provide summary products for change since only change products can easily be summarized. Beyond providing the mode for land cover and land use products, summarizing them is rather difficult.

To summarize the change layers, we use two methods: *most recent* and *most probable*. The *most recent* method chooses the year of the respective change class that occurred most recently, while the *most probable* method chooses the year of the respective change class with the highest model confidence. The former can be useful for applications that need to know the most recent year a given change class was present, while the latter is useful for applications that need to know when a given change event peaked.
For example, the time series of change model confidences, or probabilities, for a given pixel is shown in figure 8.

![LCMS Change Time Series](image)

*Figure 8. – Land Change Monitoring System change model confidence values for a single pixel.*

The *most recent* change years for this example are:

- Slow loss: 2012
- Fast loss: 2013
- Gain: 2020

The *most probable* change years are:

- Slow loss: 2011
- Fast loss: 2013
- Gain: 2015

Slow loss is used for understanding in the examples above but was not produced in the PRUSVI change product since PRUSVI exhibited limited slow loss. Generally, the two summary methods differ most for long-term change processes, such as gain and slow loss.

Ancillary information on the origin of the annual LCMS product output values is now provided as part of a QA bit layer. This layer includes whether an interpolated value was used to produce the LCMS output, the sensor, and the day of year the value came from. The QA bits are as follows:

- 1: Interpolated (0), not interpolated (1)
- 2-6: Which sensor the pixel came from
  - 4 = Landsat 4
  - 5 = Landsat 5
  - 7 = Landsat 7
  - 8 = Landsat 8
  - 21 = Sentinel 2a
  - 22 = Sentinel 2b
- 7-15: Which Julian day the pixel came from (1-365)
Bitwise operations can be leveraged to unpack the QA decimal numbers to valid pixel values for the non-interpolated data, sensor, and Julian day (see metadata for more detailed method). Table 1 shows how the bits are used in the QA Bits output image.

Table 7. – Table of how bits are used in the QA Bits output image.
