USDA Non-Discrimination Statement

In accordance with Federal civil rights law and U.S. Department of Agriculture (USDA) civil rights regulations and policies, the USDA, its Agencies, offices, and employees, and institutions participating in or administering USDA programs are prohibited from discriminating based on race, color, national origin, religion, sex, gender identity (including gender expression), sexual orientation, disability, age, marital status, family/parental status, income derived from a public assistance program, political beliefs, or reprisal or retaliation for prior civil rights activity, in any program or activity conducted or funded by USDA (not all bases apply to all programs). Remedies and complaint filing deadlines vary by program or incident.

Persons with disabilities who require alternative means of communication for program information (e.g., Braille, large print, audiotape, American Sign Language, etc.) should contact the responsible Agency or USDA's TARGET Center at (202) 720-2600 (voice and TTY) or contact USDA through the Federal Relay Service at (800) 877-8339. Additionally, program information may be made available in languages other than English.

To file a program discrimination complaint, complete the USDA Program Discrimination Complaint Form, AD-3027, found online at How to File a Program Discrimination Complaint and at any USDA office or write a letter addressed to USDA and provide in the letter all of the information requested in the form. To request a copy of the complaint form, call (866) 632-9992. Submit your completed form or letter to USDA by: (1) mail: U.S. Department of Agriculture, Office of the Assistant Secretary for Civil Rights, 1400 Independence Avenue, SW, Washington, D.C. 20250-9410; (2) fax: (202) 690-7442; or (3) email: program.intake@usda.gov.

USDA is an equal opportunity provider, employer, and lender.

Executive Summary
The National Land Cover Database (NLCD) Tree Canopy Cover (TCC) is a remote sensing-based map output produced by the United States Department of Agriculture, Forest Service (Forest Service). The 2021 NLCD TCC release includes annual maps from 2011-2021 across the Conterminous United States (CONUS), coastal Alaska, Puerto Rico and the US Virgin Islands (PRUSVI), and Hawaii. Science TCC products are also available annually from 2008 to 2021. Science and NLCD TCC products can be used in many applications including monitoring forest health, post-disturbance recovery, urban canopy distribution, and carbon accounting.

This document details the methods used to create the annual Science and NLCD TCC map products for TCC version 2021.4. A forthcoming manuscript will provide a more comprehensive summary of TCC 2021.4 background, methods, and results. These methods will be revisited with each new release to ensure they reflect the best available science. Current methods utilize Google Earth Engine (GEE) to run the Landsat-based detection of Trends in Disturbance and Recovery (LandTrendr) temporal segmentation algorithm on annual composites of Landsat and Sentinel-2 imagery. The outputs from LandTrendr are used as predictor variables in random forest models that are calibrated outside GEE using Forest Service Forest Inventory and Analysis (FIA) photo-interpreted TCC data to make wall-to-wall TCC predictions on a pixel-wise basis.

The main goal of this version of the production methods was to enable more frequent time steps, a longer temporal extent, and more coherent temporal signals in the TCC products. This goal was achieved by using GEE storage and compute capacity for image processing, and by incorporating time-series-based approaches already utilized by Forest Service programs like the Landscape Change Monitoring System (LCMS), while also ensuring the NLCD TCC product retains the level of quality expected of a product that is part of the NLCD suite.

NLCD TCC products are freely available for download on the Multi-Resolution Land Characteristics (MRLC) consortium website.

Annual Science TCC products are available for download on the FSGeodata Clearinghouse website.

Background
The Forest Service produces the NLCD TCC product as a member of the MRLC consortium (Wickham et al., 2014). The 2001 version of the NLCD TCC product was produced by the United States Geological Survey (USGS) (Homer et al., 2004). All subsequent releases have been produced by the Forest Service. This includes the 2011 and 2016 releases and the most recent 2021 release (Coulston et al., 2012; Yang et al., 2018). With each new NLCD TCC data release, previous datasets are superseded with the newest version for each map year. This follows protocols used for the NLCD Land Cover and Urban Impervious Cover datasets.

All production methods are developed as a joint effort between the NLCD TCC Science Team under the Forest Inventory and Analysis (FIA) program and the NLCD TCC Production Team at the Geospatial Technology and Applications Center (GTAC). Methods are revisited and potentially changed with each new release. To allow for easy tracking of which product version you are using, all products and documentation will share the following naming convention: YYYY.v, where “YYYY” denotes the most recent year mapped, and the “v” denotes the version of the production methods used. Version 2021.4 is the first to employ this naming convention.
Annual nationwide mapping programs are becoming more common (Brown et al., 2020; Housman et al., 2022). One goal of the TCC version 2021.4 release was to leverage Forest Service LCMS methods where appropriate. As a result, NLCD TCC now shares much of the same image inputs and image pre-processing workflows used by the Forest Service LCMS. While annual NLCD TCC products are not yet being released by MRLC, annual NLCD TCC and Science TCC products (raw direct model outputs and per-pixel model standard deviation – also referred to as “standard error”) extending from 2008-2021 are being released by the Forest Service.

Since NLCD TCC 2021.4 shares some methods with the 2016 NLCD TCC release and LCMS, this document will pull from the existing 2016 NLCD TCC methods documentation (Ruefenacht et al., 2022) as well as the LCMS methods documentation (Housman et al., 2022) when appropriate.

NLCD TCC products cover the Conterminous United States (CONUS), and outside-CONUS (OCONUS) mapping areas Coastal Alaska, Puerto Rico and US Virgin Islands (PRUSVI), and Hawaii. CONUS products will be released spring 2023, with the other study areas following in summer/fall 2023. The NLCD and Science TCC product suite includes 30 m spatial resolution maps of percent tree canopy cover from 2008-2021.

**Methods**

**Study Areas**
The 2021 TCC product suite extends across CONUS, coastal Alaska, Hawaii, and PRUSVI (figure 1).

![Figure 1. Depiction of the tree canopy cover study areas for CONUS, coastal Alaska, Hawaii, and Puerto Rico and the US Virgin Islands (PRUSVI).](image-url)
All study areas except coastal Alaska match those of NLCD land cover and urban impervious cover products, produced by USGS. Specifically, CONUS consists of the 48 contiguous states and some surrounding water. Hawaii is limited to the eight major islands: Ni’hau, Kaua‘i, O‘ahu, Moloka‘i, Lāna‘i, Kaho‘olawe, Maui, and Hawai‘i. The Puerto Rico portion of PRUSVI consists of Puerto Rico, Culebra, Vieques, and Mona, while the US Virgin Islands portion of PRUSVI consists of St. Croix, St. Thomas, and St. John. Coastal Alaska includes a 219,000 km^2 region of southeast and south-central coastal Alaska (figure 1).

**Computing Platforms**

NLCD TCC utilizes Google Earth Engine (GEE; Gorelick et al., 2017) for all remote sensing raster data acquisition and processing through an enterprise agreement between the Forest Service and Google. GEE is a parallel computing environment that provides access to many publicly available earth observation datasets, along with common data processing methods and computing infrastructure to process these data.

To maintain confidentiality of the reference data locations collected over the FIA sample grid (Bechtold and Patterson 2005), we use R (R Core Team, 2010) and the Python package Scikit-Learn (Pedregosa et al., 2011) on local compute resources at GTAC to extract predictor data over reference locations, build the random forest TCC models, and compute model and map error.

**Reference Data**

**Reference Data Collection**

Reference data were collected using high-resolution imagery and the Canopy Cover Tool, developed by the Forest Service as an ArcMap™ extension (Goeking et al., 2012; figure 2). To compute a plot’s estimated tree canopy cover percentage, a grid of 109 dots (with a spacing of 26.25 feet) are placed within a 144-foot radius circle that is centered on the plot. These 109 dots are rotated 15 degrees to avoid following linear anthropomorphic features in cardinal directions. Photo interpreters indicate whether the dot falls upon tree canopy or not and the percent tree canopy cover is calculated for the plot. Interpreters also assigned a confidence level in their photo interpretations for each plot. The plot locations used for reference data collection were located on the FIA grid (Reams et al., 2005).
Figure 2. Depiction of the Canopy Cover tool used to develop tree canopy cover reference data.

For this project, tree canopy is defined as:

- Tree – live tally trees, saplings and seedlings – where tally trees are all species listed in the FIA Master Tree Species List. This list is updated and archived according to the FIA field guide.
- Canopy – The vertically-projected polygon described by the outline of the foliage, ignoring any normal spaces occurring between the leaves of plants (Daubenmire, 1959), and ignoring overlap among multiple layers of a species.

Percent tree canopy cover is then defined as:

- The percent of systematically arranged points (109 total) within a 144-foot radius circle centered on an FIA plot that fall over tree canopy (defined above).

**Reference Data Filtering**

To minimize error in the CONUS and OCONUS reference data, we omitted any plot for the following reasons:

- Low interpreter confidence
- Spectrally unstable (possible change)
- LCMS Change (Loss or Gain)
- Plot fell over an ocean waterbody
- No cloud or cloud shadow-free spectral information available
- Reference TCC > 0 where manual image interpretation indicated TCC = 0
Of the 63,010 FIA CONUS plots, the final number of plots included as reference data was 55,356 (table 1). These plots were then randomly divided into model calibration (70%) and map error assessment (30%) groups.

For coastal Alaska, tree canopy cover data was photo-interpreted over 2,035 FIA plots. Plots over offshore water or that received a low confidence score by the photo-interpreter were discarded. The final number of plots used as reference data were 1,397 (table 1). These plots were randomly divided into model calibration (80%) and map error assessment (20%) groups.

For Hawaii, tree canopy cover was photo-interpreted over 1,284 FIA plots. For map error assessment, a random set of 325 non-FIA plots were photo-interpreted.

For PRUSVI, 1,965 FIA plots were available. We omitted plots for the following reasons:

- Outside of PRUSVI NLCD study area
- Experimental plots
- Low interpreter confidence
- Reference TCC = 0 where manual image interpretation indicated TCC > 0

To increase the total number of reference points in PRUSVI, we intensified the FIA grid to add 381 points. The final number of plots used as reference data were 980 (table 1). For map error assessment, a random set of 324 non-FIA plots were photo-interpreted.

Table 1. FIA plots were removed from reference data due to low photo-interpretation quality scores, duplicate or experimental plots, locations over oceans or unavailable data, unstable spectral data, inaccurate zero canopy photo-interpretation (PI), and PI that spectrally changed according to LCMS change data between 2009-2012 (within +- 1 year of NAIP PI acquisition window). The following tables show the number of plots removed and the final number of plots used as reference data.

**Model Predictor Data**

Our model predictor data consists of Landsat and Sentinel-2 imagery fitted by the LandTrendr temporal segmentation algorithm, topographic information from the USGS 3-Dimensional Elevation Product (3DEP), and the USDA Cropland Data Layer. Descriptions of each of these datasets are provided below.

**Remote Sensing Spectral Data**

**Data Preparation**

We use United States Geological Survey (USGS) Collection 2 Tier 1 Level 1 Landsat 4, 5, 7, 8, and 9 and Sentinel-2a and 2b level 1C top of atmosphere reflectance data, as available in GEE fall 2022. We do not use surface reflectance data because the Sentinel-2 surface reflectance data available within GEE are terrain-corrected, which makes it difficult to use with Landsat surface reflectance data that are not terrain-corrected.

For cloud masking Landsat data, we apply the CFmask cloud and cloud shadow masking algorithm (Foga et al., 2017), which is an implementation of Fmask 2.0 (Zhu and Woodcock, 2012), as well as the cloudScore algorithm (Chastain et al., 2019). For cloud masking Sentinel-2 data, we utilize the s2Cloudless algorithm (Zupanc, 2017) outputs available through GEE. We mask cloud shadows in both Landsat and Sentinel-2 using the Temporal Dark Outlier Mask (TDOM) method (Chastain et al., 2019).

All remote sensing data preparation procedures can be accessed in the GTAC GEE data processing and visualization library:

- [GeeViz Module on PyPI](#)
- [GeeViz Module on GitHub](#)

**Annual Compositing**

We utilize annual composites of the masked Landsat and Sentinel-2 data as inputs for LandTrendr. Annual composite values are the geometric medoid of all values not masked as cloud or cloud shadow from a specified date range for each year. Due to differences in data availability and seasonality, we adapt the date window range across different modeling regions (table 2).

<table>

</tbody>
</table>
The geometric medoid is the value that minimizes the sum of the square difference between the median value of each band’s values (Flood et al., 2013). This ensures that the center-most value in a multi-dimensional feature space is chosen. The value from all bands is from the same observation date. The bands that we include in the feature space are green, red, near infrared (NIR), first shortwave infrared (SWIR1), and second shortwave infrared (SWIR2). We omit the blue band because it is more prone to atmospheric scattering and can inappropriately influence the medoid algorithm. Any pixel that does not have a cloud or cloud shadow free value for a given year is left as null and excluded from the composite for that year. The 2020 composite images for CONUS and coastal Alaska are shown in figure 3 as an example.
With the workflow outlined above, two separate sets of annual composite series from 1984 to 2022 are created. The first set includes Landsat 7 from 1999-2002 when the scanline corrector worked properly. In May 2003, the Landsat 7 scanline corrector failed, introducing a stripe of missing data throughout all images. This first set does not include any Landsat 7 data with scanline correction striping. The second set utilizes Landsat 7 from 1999-2015 both with and without the scanline correction striping artifact. To minimize scanline correction striping artifacts, only SWIR1, SWIR2, normalized difference vegetation index (NDVI), normalized burn ratio (NBR), normalized difference moisture index (NDMI), and tasseled cap brightness are used. Note that the first set is different from those used for LCMS and it is used for CONUS, coastal AK, and PRUSVI study areas. Hawaii lacked sufficient Landsat 5 imagery to create composites from 2003-2013 without Landsat 7.

**Temporal Segmentation**

The goal of temporal segmentation is to identify periods of time that likely have similar vegetation cover and/or change processes. We use LandTrendr (Kennedy et al., 2010; Kennedy et al., 2018) to segment both sets of prepared composite image time series. LandTrendr requires a maximum of one observation per year (i.e., an annual composite, made from Landsat and Sentinel-2 data).

**LandTrendr Methods**

LandTrendr iteratively breaks the time series of annual composites and returns a set of segments. Each segment has a start and end year, and a start and end fitted value at the start and end vertices respectively (figure 4). From this information, we assign each band/index for each year the fitted value.
We use the GEE version of LandTrendr outlined in Kennedy et al. (2018). The parameters that are used are the same as those in Kennedy et al. (2018) (table 3). Further documentation of the LandTrendr method used can be found in the GEE documentation.

**Summary**

Figure 5 illustrates how one of our predictor variables (the normalized burn ratio (NBR)) is segmented by LandTrendr for two example pixels. The pixel depicted in the top chart shows a fire event, while the bottom chart shows insect-related tree mortality. The dark green line is the raw composite NBR value, while the lighter green line represents the fitted values we use in our models. Only the 2011 fitted LandTrendr values were used for model calibration, while all respective years were used for model application.
Figure 5. An example of raw medoid composite and LandTrendr fitted NBR values for a single pixel. The pixel depicted in the top chart shows a fire event, while the bottom chart shows insect-related tree mortality.

**Terrain Data**

We use terrain metrics to provide elevation, slope, and aspect, information to the model. The specific variables used are:

- Elevation
- Aspect
- Sine (Aspect)
- Cosine (Aspect)
- Slope

For all study areas, the 10 m USGS 3D Elevation Program (U.S. Geological Survey, 2019) was used. All resampling from 10 m to 30 m spatial resolution was performed using cubic convolution.

**Cropland Data**

For CONUS, we also use the USDA National Agricultural Statistics Service (NASS) Cropland Data Layer (CDL) cropland layers to help inform the model on locations of agricultural areas (Lin et al., 2022). For each CONUS model year (2008-2021), binary agriculture data are produced by classifying all non-tree CDL crops as agriculture, and everything else non-agriculture. No cropland layers were used for the OCONUS.

**Summary**

All variables covered in this section are utilized in the methods outlined below. Table 4 shows a full list of all predictor variables considered for modeling.
Table 4. List of NLCD TCC model predictor variables. This table depicts both annual values, which are different for each year of the analysis period, and static terrain values, which remain constant. Sets 1 and 2 both include the following sensors: Landsat 4, Landsat 5, Landsat 7, Landsat 8, Landsat 9, Sentinel 2a and Sentinel 2b.

**Modeling**

**Science TCC Product Modeling**

NLCD TCC utilizes the random forest modeling method (Breiman, 2001). Random forest randomly selects a subset of the predictor variables and training sites in many different regression trees. Each of the trees predicts a TCC value, the mean of which is used as the final modeled TCC value.

We utilize the GEE instance of random forests called “smileRandomForest” for all raster-based regression. To meet requirements to protect the confidentiality of the FIA reference data locations, all predictor data extraction and model calibration was performed locally using the sklearn.ensemble.RandomForestClassifier method. Calibrated models were then uploaded to GEE for application to the raster predictor stack.

Due to its size and wide variety of ecotones, CONUS modeling was broken up into fifty-four 480x480 km tiles. For each tile, a unique random forest model was built using 2011 fitted LandTrendr, 2011 CDL, and
terrain data. All reference data that were part of the 70 percent available for model calibration that intersected tiles within a 5x5 window around the center tile were used to train the random forest model. That model was then applied to the center tile. Figure 6 illustrates how the moving window approach covered CONUS. A moving window approach was not used for the OCONUS. For each OCONUS mapping area one random forest model was trained and applied.

These models were built on relationships between 2011 reference data and 2011 predictor data. Temporal fitting and segmenting algorithms (i.e., LandTrendr) vastly improve the signal to noise ratio in time-series built with Landsat and Sentinel-2 data. It has generally been accepted that radiometric normalization enables the spatial and temporal transfer of models, built with a limited subset of training data, to predict over additional years or locations that were not used in model calibration (Powell et al., 2010; Hansen and Loveland, 2012; Moisen et al., 2016; Vogeler et al., 2018; Potapov et al., 2022). Following this logic, we applied the 2011 model to predict TCC from 2008 to 2021. The last year of the image time series fitted by LandTrendr (2022) was not used to predict, as the last year can have more errors.

While each pixel has a mean predicted TCC value for each year, it also has a standard deviation of the predicted values from all regression trees (we refer to this as standard error). The utility of the standard error is limited since it does not account for the actual model error or the variability of that model error. To provide a depiction of the variability of expected model error we simulated a model error statistic referred to as tau, following guidance from Coulston et al. (2016). For CONUS, tau percentiles were simulated for each of the 54 tiles, and for OCONUS tau percentiles were simulated for the mapping area. The intent of tau is to provide a measure of model uncertainty. The implementation is designed to

Figure 6. Illustration of 5x5 480x480 km moving window modeling method. This frame illustrates the adjacent tiles in red where training data were pulled from, and the yellow tile in the center the model was then applied to. The raw Science 2011 TCC map is depicted as it is predicted for this tile. Note this animation uses a web Mercator projection which is not an equal area projection, so the equal area square tiles appear distorted. An animated illustration of this moving window method is available here: https://storage.googleapis.com/tcc-graphics/TCC_Tile_Animation.gif
normalize pixel-wise standard error by the simulated variance of model error. Bootstrap resampling is used to parameterize many random forest models, in which the observed and predicted values are retained for the ~37 percent holdout (typical in bootstrap sampling with replacement). Those held out pairs of observations and predictions represent a type of error assessment that can be used to define the prediction and error of new observations. In theory, the distribution of these pairwise bootstrapped holdouts can be used to build intervals to help evaluate the uncertainty or confidence around future predictions in the TCC distribution space. These tau distributions are translated to tables and provided as part of the Science TCC products.

**Science Products**

Science products consist of the mean and standard deviation (also referred to as standard error throughout the documentation of this release) of the TCC values the regression trees within the random forest model predicted (figure 7), along with the tau tables for each of the 54CONUS models and for each OCONUS model. These outputs are available annually from 2008-2021 through the Forest Service TCC distribution website.

This output is useful for anyone who prefers to introduce their own post-processing workflow and/or who needs a depiction of pixel-wise model error and model uncertainty.

![Figure 7. Example of a pixel of the raw Science TCC output. Notice values will bounce around a little each year. This pixel was initially a healthy forest, followed by a long period of gradual decline of TCC from 2015-2020. Then in late summer 2020 (2021 mapped year), this area experienced a wildfire.](image)

**NLCD TCC Post-Processing Methods**

A post-processing workflow was developed to create the final NLCD TCC products. The main workflow steps were:

- For non-urban areas:
  - Mask implausible TCC values that should be 0% TCC
  - Mask small clumps of trees
- For urban areas:
Mask areas with low TCC and high model uncertainty and simulated error in urban areas.

For all mapping areas, filter out small inter-annual fluctuations that could confound interpretations of change common in the time series of predicted TCC values.

**Separating Urban and Non-Urban Areas**

Our first goal was to mask areas with predicted TCC values greater than 0 that were likely 0. To mitigate masking highly fragmented tree canopy cover common in urban settings, we separated urban and non-urban areas. We used 2018 TIGER U.S. Census Block data, and the LCMS land use developed class as our urban mask.

**Non-Urban Non-Tree TCC Masking**

For all non-urban areas, we first created a mask annually to mitigate errors related to false positive (TCC>0%), and salt and pepper errors from tiny groups of trees or single trees in the landscape, which are harder to characterize accurately. For a given year’s TCC output, we used the following mask primitives:

- 3 year moving window of LCMS non-tree class mode
  - Any pixel where the mode of a 3-year window (+/- 1 year from year of interest) was any of the non-tree LCMS classes (any class without a tree as a primary or secondary sub-class).

- Crop mask
  - NASS CDL non-tree crop areas for the given year of interest for CONUS.
  - No data were used to identify non-tree crop in the OCONUS.

- Water mask
  - NLCD (2019 release) land cover water data from the closest year available to the year of interest for CONUS.
  - For coastal Alaska and PRUSVI the annual LCMS Landcover product water class.
  - For Hawaii the JRC Yearly Water Classification History, v1.4 (Jean-Francois Pekel et al., 2016).

Any LCMS tree pixel that fell over CDL non-tree crop (CONUS only) or water in respective water masks (all study areas) was recoded to non-tree. A minimum mapping unit, defined as tree clumps greater than 4 pixels (30x30 m) in size, using queen’s case of adjacency (9 neighbor), was used to identify salt and pepper type tree clumps outside of urban areas in the LCMS tree mask. Any clump of tree pixels less than or equal to 4 pixels was recoded to non-tree; however, non-tree clumps less than or equal to 4 pixels were not recoded to tree.

TCC pixels that intersected non-tree pixels in the non-urban non-tree mask, were set to 0% TCC (figure 8; figure 9). For coastal Alaska, trees found in the LCMS Land Cover tall shrub class were omitted from the initial LCMS non-tree masks. The 78th tau percentile was used to separate treed from non-treed pixels in the LCMS Landcover tall shrub class in coastal Alaska.
Figure 8. An example pixel where the non-urban non-tree mask filter was applied. As all years fell within the non-urban non-tree mask, the TCC values in the Science TCC product were set to 0 in the NLCD TCC product.
Urban Non-Tree TCC Masking

For urban areas, as defined above, we used a different routine to filter un-plausible false positive TCC values. No minimum mapping unit over a tree mask was used as part of the urban filter routine. First, we applied the same agriculture (CONUS only) and water masks (all mapping areas) used for each year in the non-urban masking routine. Next, we used the simulated model error statistic referred to as tau, following guidance from Coulston et al. (2016; see Modeling section above) to identify pixels insignificantly different from 0% TCC. This method simulates a distribution of error values from our reference data. For the different study areas different tau percentile values were chosen. The tau percentiles chosen were the 87th percentile value for the CONUS, 70th percentile value for coastal Alaska, 90th percentile for PRUSVI, and the 90th percentile for Hawaii. This value generally balanced commission and omission of masking non-tree areas in visual exploration of different percentile values. This tau percentile value is then multiplied by the standard deviation (also referred to as standard error in our documentation) of the TCC regression trees’ predicted values. Urban pixels were assigned to 0% TCC as follows (figure 10):

\[
\left(\text{mean}(TCC_{predicted}) - (\text{standardDeviation}(TCC_{predicted}) \times \text{tau})\right) \leq 0 \rightarrow 0\%TCC
\]
Figure 10. Urban area example from Utah, illustrating the impact of the urban low confidence filtering step. The top image shows high resolution satellite imagery for context. The middle image shows the mean TCC predictions. The bottom image shows
the filtered and masked NLCD TCC product. Notice how many higher density developed areas had somewhat high TCC values in the unfiltered TCC product. These are then all set to 0 in this filtering step.

**Temporal Filtering**

Last, we remove small inter-annual changes by only allowing for changes greater than +/-10% TCC each year, starting with a 2008-2010 median value. This filtering step can have positive and negative impacts on the final outputs, as illustrated in figure 11, but simplifies the potential use of NLCD TCC outputs for change detection.

---

*Figure 11. Comparison of the Science TCC and NLCD TCC outputs illustrating the impact of the temporal filtering routines applied. This filter is designed to prohibit any inter-annual change less than +/-10% TCC in the final NLCD TCC products. The top example illustrates the type of small inter-annual change common in the Science outputs converted to a steady signal after the filtering routine is applied. The bottom example is selected from a location that experienced a wildfire. In this second example, the filtering routine does result in the elimination of the slight decline in TCC prior to the fire year (2019).*
This post-processing workflow was applied to 2011, 2013, 2016, 2019, and 2021 Science TCC outputs to produce the final NLCD TCC product suite. The NLCD TCC will now match 54 percent of the years of the USGS NLCD products, an improvement from only a 20 percent match for the 2016 release.

**Map Error Assessment**

We conducted an independent error assessment over the 2011 NLCD TCC v2021.4 map output. For CONUS, 30 percent of our response data was withheld from model calibration to be used for assessing error. Our 2011 CONUS FIA reference data had varying spatial densities (due to different reporting needs from FIA data, different re-measurement frequencies (Reams et al., 2005), and our own filtering process (table 1)). To account for this, we estimated the area weight of each plot by computing Thiessen polygons for each plot centroid (figure 12). To avoid extremely large weights for edge plots, any plot on the edge assumed the average of the weight of neighboring non-edge plots' polygon weights.

![Figure 12. Fuzzed plot locations for an area with their computed Thiessen polygons shown in light gray. The area of each polygon around each plot was then used to weight the plot. This way a plot in a lower density area would receive a higher weight.](image)

We then computed the weighted root mean squared error (RMSE) and mean absolute error (MAE) using the response TCC value as the truth, and the final NLCD TCC 2011 map value at the pixel coincident with the subplot center of the actual FIA plot location. The 2011 CONUS-wide NLCD TCC map RMSE is 13 percent TCC and the MAE is 8 percent TCC.

For coastal Alaska, 20 percent of our response data was withheld from model calibration to be used to assess error. Since all the FIA data collected for coastal Alaska occurred on the same FIA grid system, the spatial density was sufficiently consistent to negate the need for the Thiessen polygon-based weighting method used in CONUS. The RMSE was computed directly using the holdout photo-interpreted TCC calls and the predicted TCC values. The RMSE for coastal Alaska was 19 percent.
For Hawaii and PRUSVI, an independent random sample of 325 and 324 plots were used to calculated RMSE, respectively. The RMSE for PRUSVI was 21 percent and the RMSE for Hawaii was 21 percent.
